AMERICAN CAPPED CALL OPTIONS ON DIVIDEND PAYING ASSETS*

Mark Broadie†, Jérôme Detemple‡

Abstract / Résumé

This paper addresses the problem of valuing American call options with caps on dividend paying assets. Since early exercise is allowed, the valuation problem requires the determination of optimal exercise policies. Options with two types of caps are analyzed: constant caps and caps with a constant growth rate. For constant caps the optimal exercise policy is to exercise at the first time at which the underlying asset's price equals or exceeds the minimum of the cap and the optimal exercise boundary for the corresponding uncapped option. For caps that grow at a constant rate the optimal exercise strategy can be specified by three endogeneous parameters.

La présente étude a pour objet la valorisation des options d'achat américaines avec plafonds sur les actifs générateurs de dividendes. Comme le détenteur de l'option peut l'exercer avant l'expiration, la solution au problème de valorisation exige la détermination des politiques d'exercice optimales. Deux types de plafonds sont envisagés : les plafonds constants et les plafonds dotés d'un taux de croissance constant. Lorsque le plafond est constant, la politique optimale consiste à exercer l'option dès que le prix de l'actif sous-jacent est égal ou supérieur au minimum du plafond et de la frontière d'exercice optimale de l'option non plafonnée correspondante. Lorsque le plafond croît à un taux constant, la stratégie d'exercice optimale peut être spécifiée à partir de trois paramètres endogènes.

* This paper has been presented at the 1993 Derivative Securities Symposium, 1993 Western Finance Association Meetings, 1994 American Finance Association Meetings, Baruch College, and Université de Genève. We thank the participants of the seminars, Phelim Boyle, Bjorn Flesaker, and two anonymous referees for their comments. We are especially grateful to the editor, Chi-fu Huang, for detailed suggestions which have improved this paper. Please address correspondance to Mark Broadie, 415 Uris Hall, Graduate School of Business, Columbia University, New York, NY 10027.

The valuation of American capped call options is a problem of theoretical as well as practical importance. Indeed, in the past few years several securities have been issued by financial institutions which include cap features combined with standard American call options. One example is the Mexican Index-Linked Euro Security, or "MILES". The MILES is an American call option on the dollar value of the Mexican stock index, the Bolsa Mexicana de Valores. The option is nonstandard because it has both a cap and an exercise period that is less than the full life of the option. The underlying asset is an index which involves dividend payments. The decision to exercise the option is under the control of the holder of the security.

Other examples of options with caps are the capped call (and put) options on the S&P 100 and S&P 500 indices that were introduced by the Chicago Board of Options Exchange (CBOE) in November, 1991. These capped index options combine a European exercise feature (the holder does not have the right to exercise prior to maturity) and an automatic exercise feature. The automatic exercise is triggered if the index value exceeds the cap at the close of the day. Flesarker (1992) discusses the design and valuation of capped index options. These options differ from the MILES because the holder of the option does not have any discretion in the exercise policy, i.e., they are not American options. Other examples of European capped call options include the range forward contract, collar loans, indexed notes, and index currency option notes [see Boyle and Turnbull (1989) for a description of these contracts].

The motivation for introducing capped options is clear. Written uncapped call options are inherently risky because of their unlimited liability. By way of contrast capped call options have limited liability and are therefore attractive instruments to market for an issuer or to hold short for an investor. Wide acceptance of these new securities in the marketplace, however, depends on a thorough understanding of their features and properties. Understanding valuation principles is important not only for pricing these new securities, but also for hedging the risks associated with taking positions in the securities. Because early exercise (i.e., before the option's maturity) may be beneficial with American capped call options, it is also essential to understand the structure of optimal exercise policies.

While these types of securities can be valued numerically by standard techniques, numerical results alone offer little explanation why certain exercise strategies are optimal. When standard binomial valuation procedures are applied to capped call options, the number of iterations required to obtain a desired level of accuracy is greatly increased compared to uncapped options. In this paper, optimal exercise policies and valuation formulas are derived.

Options with caps were studied by Boyle and Turnbull (1989). Their paper provides valuation
formulas for European capped options as well as insights about early exercise for American capped options. The possibility of optimal early exercise with American capped call options was recognized by Boyle and Turnbull. They point out that when the underlying asset price substantially exceeds the cap, immediate exercise dominates a waiting policy.

Barrier options are related contracts which were studied in Cox and Rubinstein (1985) and more recently in Rubinstein and Reiner (1991). Barrier options combine a European-style exercise feature (the holder does not have the right to exercise prior to maturity) and an automatic exercise feature. The automatic exercise is triggered if the price of the underlying asset reaches the barrier (cap). The automatic exercise feature is slightly different than for CBOE's capped index options, where exercise can only occur at the close of a trading day. The combination of exercise features of barrier options places them between European options and American options.

The presence of a cap on a call option complicates the valuation procedure. The floor on an option (i.e., the strike price) gives an incentive to exercise as late as possible. This is the source of the classical result that early exercise is suboptimal for American uncapped call options on non-dividend paying stocks. The American feature is worthless in this case, and American and European options have the same value. When the underlying asset pays dividends an incentive to exercise early is introduced. The optimal exercise boundary arises from the conflict between these two incentives. For standard American options without caps, the optimal exercise boundary can be written as the solution to an integral equation [see, e.g., Kim (1990) and Carr, Jarrow, and Myneni (1992)].

The introduction of a cap adds a further incentive to exercise early. On the surface, it seems that the cap could interact with the previous incentives to completely alter the form of the optimal exercise region. However, we show that the optimal exercise region is changed in a straightforward way. We show that the optimal exercise policy is to exercise at the first time at which the underlying asset's price equals or exceeds the minimum of the cap and of the optimal exercise boundary for the corresponding uncapped call option. For low and non-dividend paying assets the optimal exercise policy simplifies to exercising at the cap. When the underlying asset price follows a geometric Brownian motion process with constant proportional dividends an explicit valuation formula is given.

The valuation formula is then generalized to options with delayed exercise periods, i.e., American options that cannot be exercised before a prespecified future date. The MILES contract has a delayed exercise period, which can be viewed as a time varying or growing cap. In this case, the growing cap is a step function with a single jump. Growing caps may be preferred by investors since
the upside potential increases over time. These caps may also be attractive to issuers who can accept a larger potential liability as time passes. A step function is an extreme form of a growing cap. We proceed to analyze caps that grow at a constant rate. For these caps we derive optimal exercise strategies and show that they can be completely characterized in terms of only three endogenous parameters.

The paper is organized as follows. American capped call options with constant caps are analyzed in the next section. Results are given for finite and infinite maturity options. In Section 2 the analysis is extended to capped call options that have delayed exercise periods and to the MILES contract, i.e., a capped call option on the dollar value of an index with a delayed exercise period. The case of caps that grow at a constant rate is considered in detail in Section 3. Section 4 provides numerical results comparing European capped calls to their American counterparts. A comparison of hedge ratios is also given. Conclusions and remarks on possible extensions of the model are given in Section 5. Proofs of results and some of the more lengthy formulas are collected in the Appendix.

1. Valuation of American Capped Call Options

We consider a class of derivative securities written on a dividend paying underlying asset which may be interpreted as a stock or an index. The price of the underlying asset, $S_t$, satisfies the stochastic differential equation

$$dS_t = S_t[(\mu - \delta)dt + \sigma dW_t],$$

(1)

where $W = \{W_t, \mathcal{F}_t : t \in [0,T]\}$ is a Brownian motion process and the coefficients $\mu$, $\delta$, and $\sigma$ are constants. Equation (1) implies that the stock price follows a geometric Brownian motion (lognormal) process with a constant dividend rate of $\delta$. We also assume that funds can be invested in a riskless money market account bearing a constant positive rate of interest denoted $r$.

Let $C^k_t$ represent the value of an American capped call option at time $t$. The option has a strike price of $K$, a cap of $L$, and a maturity of $T$. Throughout the paper, we assume that $L \geq K > 0$. Exercise may take place, at the discretion of the owner of the security, at any date during the life of the option $[0,T]$. The payoff of the capped option when exercised at time $t$ is $((S_t \wedge L) - K)^+$, where the operator $x \wedge y$ denotes $\min(x, y)$ and $x^+$ denotes $\max(x, 0)$.

Let $B_t$ denote the optimal exercise boundary for an uncapped call option with the same maturity and strike price as the capped call option. That is, immediate exercise is optimal at time $t \in [0, T]$ for all prices $S_t \geq B_t$. Integral equations which implicitly define $B_t$ are given in Kim (1990) and Carr, Jarrow, and Myneni (1992).
**Theorem 1:** Consider an American call option with exercise price $K$, cap equal to $L$, and maturity $T$. Let $\tilde{B}$ denote the optimal exercise boundary of the capped option. Then, for $t \in [0, T]$,

$$\tilde{B}_t = L \land B_t.$$  

That is, immediate exercise is optimal for the capped option if $S_t \geq \tilde{B}_t$ and suboptimal if $S_t < \tilde{B}_t$.

Because of the conflicting exercise incentives provided by a floor, cap, and dividends, the optimal exercise boundary might seem to be quite complicated. However, Theorem 1 shows that the optimal exercise boundary for a capped option has a simple relationship to the optimal exercise boundary for the corresponding uncapped option. It says that the optimal exercise time for the capped option is the minimum of the first time at which the price of the underlying asset attains or exceeds the value of the cap and the first time at which exercise of the uncapped option is optimal. The shaded area in Figure 1 illustrates an *optimal exercise region*, i.e., the set of times and asset prices $(t, S_t)$ where it is optimal to exercise the capped call option.

Figure 1 ABOUT HERE

In the case of no dividends, a simple arbitrage argument shows that a stronger result holds. Namely, for a continuous time varying cap denoted $L_t$, it is not optimal to exercise at any time $t$ for which $S_t < L_t$. This result holds even if the cap declines precipitously shortly after time $t$.

For small dividend rates with a constant cap the optimal exercise policy simplifies. Recall that $B_t$ is decreasing in $t$ and $B_T = \max\{(r/\delta)K, K\}$. Hence for dividend rates $\delta \leq rK/L$, $B_t \geq L$ for all $t \in [0, T]$. In this case $\tilde{B}_t = L$, and the optimal exercise policy for the capped option is to exercise at the first time at which the price of the underlying asset equals or exceeds the value of the cap.

Once the optimal exercise policy is known it is straightforward to derive a valuation formula for the American capped call option. We first consider the special case of an infinite maturity option. Recall that the optimal exercise boundary for an infinite maturity uncapped option is a constant, which we denote $B_\infty$.

**Corollary 1** (American capped call with infinite maturity): Consider an American capped call option with infinite maturity and payoff $((S_t \land L) - K)^+$ if exercised at time $t$. Then the optimal exercise boundary of the capped option is the constant $L \land B_\infty$. That is, the optimal exercise time is $\tau = \inf\{\nu \in [t, \infty) : S_\nu \geq L \land B_\infty\}$. The value of the option at time $t$ for $S_t < L \land B_\infty$ is

$$C^i_t(S_t, K, \infty) = (L \land B_\infty - K) \left(\frac{S_t}{L \land B_\infty}\right)^{2r/\sigma^2}$$  

(2)
where \( \alpha \) is defined in (9) below. Furthermore, if the underlying asset pays no dividends, i.e., \( \delta = 0 \), then the option value simplifies to

\[
C_t^L(S_t, K, \infty) = (L - K) \frac{S_t}{L}.
\]  

(3)

In both cases, for \( S_t \geq L \land B_\infty \) the option value is \((S_t \land L) - K\).

When the option has an infinite maturity, the valuation formulas have especially simple forms. Equations (2) and (3) square with intuition in several senses. They show that the value of the infinite option is an increasing function of the cap, a decreasing function of the strike price, and is bounded above by the exercise payoff \( L - K \) and bounded below by zero.

Valuation formulas for finite maturity capped options are given next. Let \( \tau_L = \inf \{ \nu \in [t, \infty) : S_{\nu} \geq L \} \) represent the first hitting time of the set \([L, \infty)\), i.e., the first time at which the value of the underlying dividend paying asset equals or exceeds \( L \). Let \( t^* \) be defined by the solution to the equation \( B_\nu = L_\nu \) for \( \nu \in [0, T] \) if a solution exists.\(^5\) If \( B_\nu < L \) for all \( \nu \in [0, T] \) set \( t^* = 0 \) and if \( B_\nu > L \) for all \( \nu \in [0, T] \) set \( t^* = T \). Also, let \( C_t(S_t) \) denote the value of an American uncapped call option with maturity \( T \) on the same dividend paying underlying asset. Throughout the paper, \( \eta(z) \) represents the density function of a standard normal random variable and \( N(z) \) denotes the cumulative distribution function of a standard normal random variable.

**Theorem 2:** Consider an American call option with exercise price \( K \), cap equal to \( L \), and maturity \( T \). For \( S_t \geq L \land B_t \) the option value is \((S_t \land L) - K\). For \( S_t < L \land B_t \) and \( t \geq t^* \) the option value is \( C_t(S_t) \). For \( S_t < L \land B_t \) and \( t < t^* \) the option value is given by

\[
C_t^L(S_t, K, T - t) = E_t^*[e^{-r(T-t)}(S_{\tau_L} - K)1_{\{\tau_L < t^* \}}] + E_t^*[e^{-r(t^*-t)}C_t^*(S_{t^*})1_{\{t^* \leq \tau_L \}}].
\]

(4)

The valuation formula for \( C_t^L(S_t, K, T - t) \) can be written more explicitly as

\[
(L - K)\left[ \lambda_t^{2\phi/\sigma^2} N(d_0) + \lambda_t^{2\alpha/\sigma^2} N(d_0 + 2\sqrt{t^*-t}/\sigma) \right] + e^{-r(t^*-t)} \int_{x=0}^{L} C_{t^*}(x) u(x, t, t^*) \, dx
\]

(5)

where

\[
u(x, t, t^*) = \frac{1}{\chi \sigma \sqrt{t^*-t}} \left[ n(d_1(x)) - \lambda_t^{-(r - \delta)/\sigma^2} n(d_2(x)) \right]
\]

(6)

\[
d_0 = \frac{1}{\sigma \sqrt{t^*-t}} [\log(\lambda_t) - f(t^*-t)]
\]

(7)

\[
d_1(x) = \frac{1}{\sigma \sqrt{t^*-t}} [\pm \log(\lambda_t) - \log(L) + \log(x) + b(t^*-t)]
\]

(8)

\[
b = \delta - r + \frac{1}{2} \sigma^2, \quad f = \sqrt{b^2 + 2r \sigma^2}, \quad \phi = \frac{1}{2} (b - f), \quad \alpha = \frac{1}{2} (b + f), \text{ and } \lambda_t = S_t/L.
\]

(9)
In Theorem 2 and elsewhere in the paper, $E_t^*$ denotes the expectation operator with respect to the equivalent (risk neutral) martingale measure and the subscript $t$ denotes conditioning on the information at date $t$. The risk neutral representation formula in equation (4) is standard [see, for instance, Harrison and Kreps (1979)].

When the dividend rate is sufficiently small the optimal exercise boundary for the uncapped option lies above the cap. In particular, when $\delta \leq rK/L$, $B_\nu \geq L$ for all $\nu \in [0, T]$. In this case, $t^* = T$, the optimal exercise policy is to exercise at the cap, and equation (5) can be written more explicitly. The resulting expression for the option value is given next in Corollary 2. Equation (10) was stated in Rubinstein and Reiner (1991) for the value of a capped option with automatic exercise at the cap.

**Corollary 2** (American capped call valuation with low dividends): Suppose that the underlying asset's price follows the geometric Brownian motion process specified in equation (1). Also, suppose that $\delta \leq rK/L$. Then the value of an American capped call option, for $S_t \leq L$ and $t \in [0, T]$, is

\[
C_t^A(S_t, K, T - t) = (L - K) \left[ \Lambda_t^{2\phi/\sigma^2} N(d_0) + \Lambda_t^{2\alpha/\sigma^2} N(d_0 + 2f\sqrt{T - t}/\sigma) \right]
+ S_t e^{-\delta(T-t)} \left[ N(d_1^L(L) - \sigma\sqrt{T - t}) - N(d_1^L(K) - \sigma\sqrt{T - t}) \right]
- \Lambda_t^{-2(r-\delta)/\sigma^2} L e^{-\delta(T-t)} \left[ N(d_1^L(L) - \sigma\sqrt{T - t}) - N(d_1^L(K) - \sigma\sqrt{T - t}) \right]
- Ke^{-r(T-t)} \left[ N(d_1^L(L)) - N(d_1^L(K)) - \Lambda_t^{1-2(r-\delta)/\sigma^2} [N(d_1^L(L)) - N(d_1^L(K))] \right].
\] (10)

In (10) the expressions for $d_0$ and $d_1^L(x)$ are the same as in (7) and (8) but with $T - t$ replacing $t^* - t$. The expressions for $b$, $f$, $\phi$, $\alpha$, and $\Lambda_t$ are the same as in (9).

**Corollary 3** (European capped call valuation): Let $C_t^E(S_t, L, K, T - t)$ represent the value of an option at time $t$ that has a strike price of $K$, a cap of $L$, a maturity of $T$, and which cannot be exercised until maturity. Then the value of this European capped call is given by

\[
C_t^E(S_t, L, K, T - t) = S_t e^{-\delta(T-t)} \left[ N(d_1^L(L) - \sigma\sqrt{T - t}) - N(d_1^L(K) - \sigma\sqrt{T - t}) \right]
- Ke^{-r(T-t)} \left[ 1 - N(d_1^L(K)) \right] + Le^{-\delta(T-t)} \left[ 1 - N(d_1^L(L)) \right].
\] (11)

The expression for $d_1^L(x)$ is the same as in (8) but with $T - t$ replacing $t^* - t$.

Since the European capped call does not allow for early exercise, its price is a lower bound on the price of the American capped call option. That is, $C_t^E \leq C_t^A$. If $L \uparrow \infty$ in equation (11) then

\[
C_t^E(S_t, \infty, K, T - t) = S_t e^{-\delta(T-t)} [1 - N(d_1^L(K) - \sigma\sqrt{T - t})] - Ke^{-r(T-t)} [1 - N(d_1^L(K))],
\] (12)
which is the Black-Scholes European option formula adjusted for dividends [Black and Scholes (1973)].

2. American Capped Calls with Delayed Exercise Periods

Some American capped call options, such as the MILES contract, involve restrictions on the time period in which exercise is allowed. If the underlying stock price follows a geometric Brownian motion process, Theorem 2 can be generalized to handle the delayed exercise period.

**Theorem 3** (American capped call with delayed exercise period): Suppose that the underlying asset's price follows a geometric Brownian motion process and consider an American capped call option with exercise period equal to \([t_e, T]\). The value at time \(t \leq t_e\) is

\[
C^t_e (S_t, T - t, t_e) = (L - K) e^{-r(t_e - t)} E_t^* \left[ 1 \{ S_{t_e} \geq L \} \right] + e^{-r(t_e - t)} E_t^* \left[ C^t_e (S_{t_e}, T - t_e) 1 \{ S_{t_e} < L \} \right] \\
= (L - K) e^{-r(t_e - t)} \left[ 1 - N (d_1 (L, t_e - t)) \right] \\
+ e^{-r(t_e - t)} \int_{z = -\infty}^{d_1 (L, t_e - t)} C^t_e (S_{t_e} e^{(r-\frac{1}{2} \sigma^2)(t_e - t) + \sigma z \sqrt{t_e - t}}, T - t_e) n(z) dz. \tag{13}
\]

In (13), \(C^t_e (S_{t_e}, T - t_e)\) denotes the value of the American capped call option from equation (5) with \(T - t_e\) replacing \(T - t\) and \(\max(t^*, t_e)\) replacing \(t^*\) and where \(d_1 (x, t_e - t)\) is given in (8) with \(t_e - t\) replacing \(t^* - t\).

The optimal exercise policy is to exercise at time \(t_e\) if \(S_{t_e} \geq L \land B_t\). Otherwise, exercise at the first time after \(t_e\) that \(S_t\) reaches \(L \land B_t\) and if this does not occur then exercise at time \(T\). The formula given in (13) simplifies when the maturity of the contract is infinite.

**Capped Call Options on the Dollar Value of an Index**

The MILES security is an American capped call option on the dollar value of the Mexican stock index with a delayed exercise period. The previous analysis is applied to this type of security next.

Let \(S_t = e_t M_t\) represent the dollar value of the Mexican stock index, where \(e_t\) is the dollar-peso (S/peso) exchange rate and \(M_t\) is the value in pesos of the Mexican stock index (all at time \(t\)). Suppose that \(e_t\) and \(M_t\) follow the geometric Brownian motion processes

\[
de_t = e_t [ \mu_e dt + \sigma_{e_1} dW_{1t} + \sigma_{e_2} dW_{2t} ] \\
dM_t = M_t [(\mu_M - \delta_M) dt + \sigma_{M_1} dW_{1t} + \sigma_{M_2} dW_{2t}].
\]

where the volatility coefficients \(\sigma_{e_1}, \sigma_{e_2}, \sigma_{M_1},\) and \(\sigma_{M_2}\) are constant, the drifts \(\mu_e\) and \(\mu_M\) are constant, \(\delta_M\) is the constant dividend rate of the Mexican index, and \(W_{1t}\) and \(W_{2t}\) are independent Brownian motion processes.
With these assumptions, Itô’s lemma implies that the dollar value of the Mexican index satisfies

\[ dS_t = S_t \left[ (\mu_e + \mu_M - \delta_M + c)dt + (\sigma_{e_1} + \sigma_{M_1})dW_{1t} + (\sigma_{e_2} + \sigma_{M_2})dW_{2t} \right], \]

where \( c = \sigma_{e_1} \sigma_{M_1} + \sigma_{e_2} \sigma_{M_2} \) is the (local) correlation between the processes \( e \) and \( M \).

Since the volatility coefficients are assumed to be constant, the only risk which matters is

\[ dW_t = \frac{1}{\sqrt{(\sigma_{e_1} + \sigma_{M_1})^2 + (\sigma_{e_2} + \sigma_{M_2})^2}} \left[ (\sigma_{e_1} + \sigma_{M_1})dW_{1t} + (\sigma_{e_2} + \sigma_{M_2})dW_{2t} \right], \]

which is a Brownian motion process. This risk can be hedged away by trading in the dollar value of the index. Hence formula (13) of Theorem 3 applies with \( \sigma = \sqrt{(\sigma_{e_1} + \sigma_{M_1})^2 + (\sigma_{e_2} + \sigma_{M_2})^2} \).

### 3. Caps with a Constant Growth Rate

The MILES option contract has a delayed exercise period which can be viewed as a time varying cap. In this case, the cap is a step function with a single jump. Options with time varying caps, more specifically, growing caps, may be preferred by investors over constant caps. Increasing caps enable investors to capture more upside potential and so may increase the attractiveness of the contract from their point of view. Also issuers may be prepared to accept an increasing potential liability as time passes in return for a higher premium today. In this section we analyze time varying caps that grow at a constant rate \( g \geq 0 \). That is, the cap as a function of time is

\[ L_t = L_0 e^{gt}, \quad (14) \]

where we assume \( L_0 > K \).

For time varying caps given by equation (14), the optimal exercise policy depends on three parameters. To define the policy, recall that \( B_t \) denotes the optimal exercise boundary for an uncapped call option with the same maturity and strike price as the capped call option. Let \( t^* \) be defined by the solution to the equation \( B_\nu = L_\nu \) for \( \nu \in [0,T] \) if a solution exists. If \( B_\nu < L_\nu \) for all \( \nu \in [0,T] \) set \( t^* = 0 \) and if \( B_\nu > L_\nu \) for all \( \nu \in [t,T] \) set \( t^* = T \).

**Definition 1 (\((t_e, t^*, t_f)\) Exercise Policy):** Let \( t_e \) and \( t_f \) satisfy \( 0 \leq t_e \leq t_f \leq T \) and \( t_e \leq t^* \leq T \). Define the stopping time \( \tau_1 \) by \( \inf \{ \nu \in [t_e, t_f] : S_\nu = L_\nu \} \) or if no such \( \nu \) exists set \( \tau_1 = T \). Set the stopping time \( \tau_2 \) equal to \( t_f \) if \( S_{t_f} \geq L_{t_f} \) otherwise set \( \tau_2 = T \). Define the stopping time \( \tau_3 \) by \( \inf \{ \nu \in [t^*, T] : S_\nu = B_\nu \} \) or if no such \( \nu \) exists set \( \tau_3 = T \). An exercise policy is a \((t_e, t^*, t_f)\) policy if the option is exercised at the stopping time \( \min(\tau_1, \tau_2, \tau_3) \).
A typical exercise region corresponding to a \((t_e, r, t_f)\) exercise policy is illustrated in Figure 2. The exercise region is indicated by the shaded area together with the darker line segment joining \(L_{t_e}\) to \(L_{r}\). If a \((t_e, r, t_f)\) policy is optimal, then it is not optimal to exercise prior to \(t_e\) even if the underlying asset’s price equals the cap. Prior to \(t_f\) it is not optimal to exercise if the underlying asset’s price is strictly above the cap. The shaded region from \(t_f\) to \(T\) collapses to a vertical line when \(t_f = T\). In the case of a constant cap, \(t_e = t_f = 0\), and the optimal policy simplifies to the one described in Theorem 1.

Figure 2 ABOUT HERE

The main results are given next. The optimal exercise policy is characterized in Theorem 4. A formula for valuing a capped call option for any \((t_e, r, t_f)\) policy is given in Theorem 5. Finally, equations characterizing the optimal values of \(t_e\) and \(t_f\) are given in Theorem 6.

**Theorem 4:** Consider an American call option with exercise price \(K\), cap given by equation (14), and maturity \(T\). Then the optimal exercise policy is a \((t_e, r, t_f)\) policy.

In the absence of dividends, \(B_t = \infty\) for all \(t\) and \(r = T\). In this case, Theorem 4 shows that the optimal exercise policy reduces to a two parameter \((t_e, t_f)\) policy where exercise below the cap is not optimal.

Some intuition behind Theorem 4 follows. It is shown in the proof of Theorem 6 that the present value at time \(t\) of \(L_v - K\) is strictly increasing with respect to \(v\) up to some time \(t_f^*\) (defined in equation (18) below) and strictly decreasing thereafter. Hence a waiting strategy is optimal if \(S_t > L_t\) and \(t < t_f^*\) while immediate exercise is optimal if \(S_t \leq L_t\) and \(t \geq t_f^*\). If \(r \leq t \leq T\) and \(B_t = S_t \leq L_t\) then exercise is optimal. This follows since exercise is optimal for an uncapped option and since the holder of the capped option can attain (but cannot improve upon) this value by exercising immediately. If \(S_t < L_t \cap B_t\) then immediate exercise is suboptimal by an argument similar to the one in the proof of Theorem 1.

Theorem 5 gives a valuation formula for a capped call option for a given \((t_e, r, t_f)\) exercise policy.

**Theorem 5:** Consider an American call option with exercise price \(K\), cap given by equation (14), and maturity \(T\). Suppose that a \((t_e, r, t_f)\) exercise policy is followed for some fixed values of \(t_e\) and \(t_f\). The value at time \(t \leq t_e\) corresponding to this policy is given by

\[
C^*_t(t_e, r, t_f) = E^*_t \left[ e^{-r(t_e-t)} \left\{ C^u_{t_e, t_f} 1_{\{S_{t_e} > L_{t_e}\}} + C^d_{t_e, r} 1_{\{S_{t_e} \leq L_{t_e}\}} \right\} \right]
\]
\[
= e^{-r(t_e-t)} \int_{z=-d_2}^{\infty} C_u^{t,f}(L_{t_e}, \lambda t e^{-b(t_e-t)} + \sigma z \sqrt{t_e-t}, t_f - t_e) n(z) \, dz \\
+ e^{-r(t_e-t)} \int_{z=-\infty}^{-d_2} C_d^{t*,t}(L_{t_e}, \lambda t e^{-b(t_e-t)} + \sigma z \sqrt{t_e-t}, t^* - t_e) n(z) \, dz,
\]
where \( \lambda_t = S_t / L_t \), \( \tilde{b} = \gamma + \delta - r + \frac{1}{2} \sigma^2 \), \( \tilde{d}_2^2(\lambda_t, t_e - t) = [\log(\lambda_t) - \tilde{b}(t_e - t)] / (\sigma \sqrt{t_e - t}) \), and \( C_u^{t,f} \)
and \( C_d^{t*,t} \) are defined below.

At time \( t_e \) with \( S_{t_e} > L_{t_e} \), the value corresponding to the \( (t_e, t^*, t_f) \) policy is independent of \( t^* \)
and is given by \( C_u^{t,f} \) where

\[
C_u^{t,f}(L_{t_e}, \lambda t_e, t_f - t_e) = L_{t_e} \left[ \lambda_t^{2\phi / \sigma^2} N(-\tilde{d}_0) + \lambda_t^{2}\alpha / \sigma^2 N(-d_0 - 2\tilde{f}(t_f - t_e) / \sigma) \right] \\
- K \left[ \lambda_t^{2\phi / \sigma^2} N(-d_0) + \lambda_t^{2}\alpha / \sigma^2 N(-d_0 - 2f(t_f - t_e) / \sigma) \right] \\
+ \left[ L_{t_e} e^{\theta(t_f - t_e)} - K \right] e^{-r(t_f - t_e)} \left[ N(d^*_2) - \lambda_t^{1+2(\psi - \phi) / \sigma^2} N(d^*_1) \right].
\]

and where \( \lambda_t = S_t / L_t \), \( \tilde{b} = \gamma + \delta - r + \frac{1}{2} \sigma^2 \), \( d_0 = [\log(\lambda_t) - f(t_f - t_e)] / (\sigma \sqrt{t_f - t_e}) \), \( \tilde{d}_0 = [\log(\lambda_t) - \tilde{f}(t_f - t_e)] / (\sigma \sqrt{t_f - t_e}) \), \( f = (\tilde{b}^2 + 2\sigma^2 r)^{1/2} \), \( \tilde{f} = (\tilde{b}^2 + 2\sigma^2 (r - \gamma))^ {1/2} \), \( \phi = \frac{1}{2} (\tilde{b} - \tilde{f}) \), \( \tilde{\phi} = \frac{1}{2} (\tilde{b} + \tilde{f}) \), \( \alpha = \frac{1}{2} (\tilde{b} + \tilde{f}) \), and \( d^*_2 = [\pm \log(\lambda_t) - \tilde{b}(t_f - t_e)] / (\sigma \sqrt{t_f - t_e}) \).

At time \( t_e \) with \( S_{t_e} \leq L_{t_e} \), the value corresponding to the \( (t_e, t^*, t_f) \) policy is given by \( C_d^{t*,t} \) where

\[
C_d^{t*,t}(L_{t_e}, \lambda t_e, t^* - t_e) = L_{t_e} \left[ \lambda_t^{2\phi / \sigma^2} N(-\tilde{d}_0) + \lambda_t^{2}\alpha / \sigma^2 N(d_0 + 2\tilde{f}(t^* - t_e) / \sigma) \right] \\
- K \left[ \lambda_t^{2\phi / \sigma^2} N(d_0) + \lambda_t^{2}\alpha / \sigma^2 N(d_0 + 2f(t^* - t_e) / \sigma) \right] \\
+ \int_{0}^{t^*} e^{-r(t^* - x)} C_t^*(x) \tilde{u}(x, t_e, t^*) \, dx
\]
and where \( \tilde{u}(x, t_e, t^*) = [n(d^*_1(x)) - \lambda_t^{1+2(r-\gamma) / \sigma^2} n(d^*_1(\lambda_t x))] / (x \sigma \sqrt{t^* - t_e}) \), \( d^*_1(x) = [\pm \log(\lambda_t) - \log(L_t) + \log(x) + (\tilde{b} - \gamma)(t^* - t_e)] / (\sigma \sqrt{t^* - t_e}) \), \( d_0 = [\log(\lambda_t) - f(t^* - t_e)] / (\sigma \sqrt{t^* - t_e}) \), \( \tilde{d}_0 = [\log(\lambda_t) - \tilde{f}(t^* - t_e)] / (\sigma \sqrt{t^* - t_e}) \).

The value at time \( t \leq t_e \) under the \( (t_e, t^*, t_f) \) policy is the present value of the corresponding policy at time \( t_e \). This present value is the risk-neutral probability weighted average of the possible values on the event \( \{S_{t_e} > L_{t_e}\} \) and the event \( \{S_{t_e} \leq L_{t_e}\} \). This observation leads to equation (15).

Theorem 6 characterizes the optimal values of \( t_e \) and \( t_f \) in a \( (t_e, t^*, t_f) \) exercise policy.

**Theorem 6:** Consider an American call option with exercise price \( K \), cap given by equation (14), and maturity \( T \). Let \( t_f^* \) denote the optimal value of \( t_f \) in a \( (t_e, t^*, t_f) \) policy. Then \( t_f^* \) is given by

\[
t_f^* = \arg\max_{0 \leq s \leq T} e^{-r s} [L_0 e^{\theta s} - K].
\]
In particular, if
\[
(g - r)L_0e^{gT} + rK \geq 0
\] (19)
then \(t^*_f = T\). Also, if
\[
(g - r)L_0 + rK \leq 0
\] (20)
then \(t^*_f = 0\). Otherwise, \(0 < t^*_f < T\) and \(t^*_f\) is given by
\[
t^*_f = \frac{1}{g} \log \left( \frac{rK}{(r-g)L_0} \right).
\] (21)

Let \(t^*_e\) denote the optimal value of \(t_e\) in a \((t_e, t^*_t, t^*_f)\) exercise policy. The following conditions are satisfied by \(t^*_e\). First, if \(0 < t^*_e < t^*_t \wedge t^*_f\), then \(t^*_e\) is a solution to equation (22):
\[
\begin{align*}
&\int_{-\infty}^{\infty} \left[ -rC^u_{t_e,t^*_f} + gL_{t_e} \frac{\partial C^u_{t_e,t^*_f}}{\partial L_{t_e}} - (\hat{b} - \frac{1}{2} \frac{\sigma^2}{\sqrt{t_e}})\lambda_{t_e} \frac{\partial C^u_{t_e,t^*_f}}{\partial \lambda_{t_e}} - \frac{\partial C^u_{t_e,t^*_f}}{\partial (t^*_f - t_e)} \right] n(z)dz \\
&+ \int_{-\infty}^{\infty} \left[ -rC^d_{t_e,t^*_t} + gL_{t_e} \frac{\partial C^d_{t_e,t^*_t}}{\partial L_{t_e}} - (\hat{b} - \frac{1}{2} \frac{\sigma^2}{\sqrt{t_e}})\lambda_{t_e} \frac{\partial C^d_{t_e,t^*_t}}{\partial \lambda_{t_e}} - \frac{\partial C^d_{t_e,t^*_t}}{\partial (t^*_t - t_e)} \right] n(z)dz = 0
\end{align*}
\] (22)
Second, if \(t^*_e = t^*_t \wedge t^*_f\) then the lefthand side of (22) is nonnegative. Third, if \(t^*_e = 0\), the lefthand side of equation (22) has a nonpositive limit as \(t_e \downarrow 0\).

The value of the American option at time \(t \leq t^*_e\) is then given by equation (15) evaluated at \(t_e = t^*_e\) and \(t_f = t^*_f\).

Theorem 6 specifies a three step procedure for valuing American capped call options where the cap has a constant growth rate. First, \(t^*_f\) is found, then \(t^*_e\) is found, and finally the option value is determined. The optimal value \(t^*_e\) solves (18). Note that if \(g \geq r\) then condition (19) holds and \(t^*_f = T\). The optimal \(t^*_e\) is the time that maximizes the option value given in equation (15) when \(t_f = t^*_f\).

For interior solutions, i.e., when \(0 < t^*_e < t^*_t \wedge t^*_f\), the optimal \(t^*_e\) solves \(\partial C^l(t_e, t^*_t, t^*_f)/\partial t_e \big|_{t_e=t^*_e} = 0\). This optimal time balances the marginal benefit (or loss) of increasing \(t_e\) on the event \(\{S_{t_e} > L_{t_e}\}\) with the marginal loss (or benefit) on the event \(\{S_{t_e} \leq L_{t_e}\}\). For boundary solutions, i.e., when \(t^*_e = 0\) or \(t^*_e = t^*_t \wedge t^*_f\), the equality of the marginal benefit to the marginal loss is replaced by the appropriate inequality. Once \(t^*_e\) and \(t^*_f\) are determined, the option value is given by equation (15).

Equation (21) reveals how \(t^*_f\) depends on the parameters \(r, g, K,\) and \(L_0\). First, the optimal time \(t^*_f\) is independent of \(\sigma\) and \(\delta\). Also, a decrease in the riskless rate \(r\) or an increase in the ratio \(K/L_0\) will increase \(t^*_f\). An increase in the rate of growth \(g\) increases \(t^*_f\) if and only if \(t^*_f < g/(r-g)\).

Numerical results are given in the next section. These results indicate that the magnitude of the loss when following the policy of exercising at the cap instead of the optimal \((t^*_e, t^*_t, t^*_f)\) policy can be substantial. Additional results illustrate how \(t^*_e\) varies with \(g\) and \(\sigma\).
4. Computational Results

In this section we provide computational results using the valuation formulas derived in this paper. The results are used to qualitatively compare the behavior of capped versus uncapped and American versus European option values.

In the presence of dividends, the valuation formulas (5), (13), and (17) can be difficult to evaluate. Broadie and Detemple (1993b) give a fast way to approximate the American option values which appear in (5), (13), and (17). However, since the valuation equations involve integrals of American option values, a standard binomial, multinomial, or finite difference procedure might be more effective for computing certain capped option values. Thus, to simplify the computations and presentation, we consider the case of no dividends (i.e., \( \delta = 0 \)) throughout this section.

Comparison of Option Prices and the Early Exercise Premium

Figure 3 shows a comparison between: (i) standard European uncapped call option, (ii) American capped call option, (iii) American capped call option with delayed exercise period, and (iv) European capped call option. The option values are computed from equations (12), (10), (13), and (11) for options (i) - (iv), respectively. The parameters for the comparison are \( r = 0.05, \sigma = 0.2, T = 1, t = 0, K = 30, L = 60, \) and \( t_e = 0.5 \) (for option (iii)). The option values are plotted versus \( S_0 \), where \( S_0 \) ranges from 35 to 75.

Since option values are increasing functions of the cap, it must be that the option values satisfy (i) \( \geq \) (ii) \( \geq \) (iii) \( \geq \) (iv). This ordering of option values is illustrated in Figure 3. For stock values well below the cap, i.e., for \( S_0 \ll L \), the four option values are nearly identical. This makes sense, since the probability of the stock price exceeding the cap by maturity approaches zero as \( S_0 \downarrow 0 \).

The early exercise premium is the difference between the American and European option values. For uncapped call options on non-dividend paying assets the early exercise premium is zero, i.e., early exercise is not optimal. For capped call options, the early exercise premium is positive, i.e., the value of an American option exceeds its European counterpart. Table 1 illustrates the magnitude of the early exercise premium for the previous parameter values. As shown in the last two columns of Table 1, the early exercise premium first increases and then decreases as the initial stock price rises. When the stock price is near the cap, the early exercise premium is nearly 20% of the value of the European option.

Table 1 ABOUT HERE
Hedging American Capped Call Options

The valuation formulas derived in the paper are important to the issuers and holders of capped call options not only for pricing but also for hedging. The valuation formulas permit a straightforward and efficient computation of hedging strategies designed to eliminate the risk inherent in a position in these contracts.

Table 2 illustrates how the hedge ratios, $\partial C / \partial S$, depend on the current stock price, $S_0$. The hedge ratios of all four options are similar for $S_0 \ll L$. For $S_0 \gg L$, the hedge ratio of option (i) approaches one, (ii) is zero and (iii) and (iv) approach zero.

Table 2 ABOUT HERE

The hedge ratios in Table 2 for the American contract (column (iii)) may differ quite significantly from those for the European contract (column (iv)). For example, when the stock price is $50$ the respective hedge ratios are 0.94 and 0.71. If the stock price increases to $65$, the hedge ratios fall to 0 and 0.23, respectively. Hence, using hedge ratios based on European formulas as an approximation would leave the hedger exposed to significant risk associated with the fluctuation in the underlying asset value.

Valuing Caps with a Constant Growth Rate

We consider an option with parameter values: $g = r = 0.10$, $\sigma = 0.05$, $T = 1$, $t = 0$, $K = 30$, $S_0 = 60$, and $L = 60$. Since $g = r$, condition (19) in Theorem 4 implies that $t^*_f = T$. Figure 4 plots $C^L_0(t_e, t^*, t^*_f)$ for $t_e$ ranging from 0 to $T$. Since $\delta = 0$, $t^* = T$. For $t_e = 0$, $C^L_0(t_e, t^*, t^*_f) = 30$ because the exercise policy calls for immediate exercise. For $t_e = T$, $C^L_0(t_e, t^*, t^*_f)$ is the value of a European capped call option with cap $L_T = L_0e^{\theta T}$. For these parameters, this gives $C^L_0(1, 1) = 31.66$. The optimal value of $t_e$ is $t^*_e = 0.88$ and the option value is $C^L_0 = C^L_0(t^*_e, t^*, t^*_f) = 31.68$. The policy of exercising immediately would result in a loss of over 5% of the value of the option.

Figure 4 ABOUT HERE

Figure 5 ABOUT HERE

Figure 5 shows how $t^*_e$ varies with the growth rate of the cap, $g$, and with volatility $\sigma$. The parameter values are the same as in the previous example, except for $g$ which ranges from 0.05 to 0.195, and $\sigma$ which ranges from 0.03 to 0.09. In this example, $t^*_e = 0$ for low growth rates and $t^*_e$ increases as $g$ increases. The volatility of the underlying asset has the opposite effect, i.e., $t^*_e$
decreases as $\sigma$ increases. For all of these parameter values, $t_f^* = T$. The parameter $t_f^*$ becomes less than $T$ for smaller values of $g$. For example, suppose that $r = 0.05$, $L_0 = 60$, $K = 30$, $T = 1$. Then for $g = 0.0255$, $t_f^* = 0.79$. As $g$ decreases, $t_f^*$ decreases to zero. As $g$ increases, $t_f^*$ increases to $T$.

5. Conclusions

This paper focused on the problem of valuing American call options with caps. Since early exercise is allowed, the valuation problem requires the determination of optimal exercise policies. The proof of Theorem 2 showed that early exercise is not optimal whenever the underlying asset's value is below the minimum of the cap and the optimal exercise boundary for the corresponding uncapped option. When the cap is constant and the dividend rate satisfies $\delta \leq rK/L$, it is optimal to exercise at the first time that the price equals or exceeds the cap.

Once the form of the optimal exercise policy is known, a valuation formula for options with delayed exercise periods can be derived. In Section 2, a valuation formula was given for the MILFS option contract. A delayed exercise period is one example of a time varying cap. In Section 3 time varying caps with constant growth rates were analyzed. For these caps, the optimal exercise strategy is given by three endogenous parameters. The exact form of the optimal policy was given in Theorem 4. In part, it says that it is not optimal to exercise prior to time $t_e^*$ no matter what is the value of the underlying asset. This differs from uncapped call options on dividend paying assets which should be exercised when the value of the underlying asset is sufficiently large.

Computational results were given in Section 4. A comparison of hedge ratios in Table 2 showed similar hedge ratios for capped and uncapped call options when the underlying asset's price is well below the cap. However, as the price increases toward the cap, the hedge ratios differ significantly. For caps with a constant growth rate, optimal exercise parameters $t_e^*$ and $t_f^*$ were computed. The dependence of $t_e^*$ on $g$ and $\sigma$ was also illustrated.

One issue for future analysis is the incorporation of stochastic volatilities into the valuation equations. This may be important in view of the empirical evidence which suggests that volatilities are time varying. Another interesting question is the optimality of caps and the design of capped option contracts taking into consideration the interests of the owner and the issuer.
Appendix: Proofs of Theorems

This Appendix gives proofs of all of the results in the paper. In addition, some of the more lengthy formulas not given in the main text are stated here. We begin by proving Theorem 1.

**Proof of Theorem 1:** Clearly when \( S_t > L \land B_t \) immediate exercise is optimal. Now suppose \( S_t < L \land B_t \) and \( L \geq (r/\delta)K \). In this case there always exists an (uncapped) American option with a shorter maturity \( T_0 \), with \( t < T_0 \leq T \), such that its optimal exercise boundary \( B^0 \) satisfies

\[
S_t < B^0_t \leq L \land B_t. \tag{23}
\]

See Figure 6 for an illustration. Since early exercise is suboptimal for this \( T_0 \) maturity option, its value strictly exceeds \( S_t - K \). From equation (23), this exercise policy is admissible for the capped option. Hence \( C^L_t > S_t - K \) and early exercise is suboptimal for the capped option.

Figure 6 ABOUT HERE

Suppose now that \( S_t < L \land B_t \) and \( L < (r/\delta)K \). In this case, an investor could purchase one call, short one share of stock, and invest the proceeds, i.e., lend \( K \), in the money market account which accrues interest at a rate \( r \). If immediate exercise were optimal, then the total cash flow from these transactions at date \( t \) would be zero. Now suppose that the call is exercised at time \( \tau \) defined by \( \tau = T_0 \land \tau_L \), where \( \tau_L \) is the hitting time of the cap. Then the net cash flow at time \( \tau \) would be

\[
(K - S_\tau)1_{\{S_\tau \leq K\}} + \int_{\tau = t}^{\tau} (rK - \delta S_\nu)e^{r(\tau - \nu)}d\nu.
\]

Clearly \( (K - S_\tau)1_{\{S_\tau \leq K\}} \geq 0 \). Since \( S_\nu \leq L < (r/\delta)K \), for \( \nu < \tau \), we have \( rK - \delta S_\nu > 0 \) for \( \nu < \tau \). Hence the integral \( \int_{\nu = t}^{\tau} (rK - \delta S_\nu)e^{r(\tau - \nu)}d\nu \) > 0 (probability a.s.). Thus for the value of the call to be consistent with no-arbitrage, immediate exercise at time \( t \) cannot be optimal. That is, \( C^L_t > S_t - K \).

\[\star\]

To prove Corollary 1, Theorem 2, Corollary 2 and later results for caps with constant growth rates, we first state three auxiliary lemmas. These lemmas characterize first passage times of sets with exponential boundaries when the asset price follows a geometric Brownian motion process. The results complement those of Black and Cox (1976) who characterize the first passage time of the set \([0, L]\) when the stock price starts above the cap, i.e., \( S_t > L \). Equation (24) below can be derived from equation (7) on p. 356 of Black and Cox (1976) by an appropriate change of variables.
Lemma 1: Suppose $S_t$ satisfies the stochastic differential equation

$$dS_t = S_t[(r - \delta)dt + \sigma dW_t].$$

For $A \leq B$, define $U(S_t, A, B, t, T)$ to be $P[S_T \leq A$ and $S_\nu < B$ for $\nu \in [t, T)]$. Then

$$U(S_t, A, B, t, T) = N(d(A)) - \left(\frac{S_t}{B}\right)^{1-2(r-\delta)/\sigma^2} N(d(A, B))$$

(24)

when $S_t \leq B$ and $t \in [0, T]$, where

$$d(A) = \frac{1}{\sigma \sqrt{T-t}} \left[ \log(A) - \log(S_t) + (\delta - r + \frac{1}{2} \sigma^2)(T-t) \right]$$

$$d(A, B) = \frac{1}{\sigma \sqrt{T-t}} \left[ \log(S_t) + \log(A) - 2 \log(B) + (\delta - r + \frac{1}{2} \sigma^2)(T-t) \right].$$

Lemma 2: Suppose that the cap is given by $L_T = L_0 e^{\delta t}$ and $\tau_L$ represents the first time at which $S_t$ reaches $L_t$. The distribution of the first passage time is

$$P[\tau_L \geq T] = \begin{cases} 
N(-\tilde{d}_2^+) - \lambda_t^{1+2(\delta + \lambda T)/\sigma^2} N(-\tilde{d}_2^-) & \text{if } S_t \leq L_T \\
\lambda_t^{1+2(\delta + \lambda T)/\sigma^2} N(\tilde{d}_2^+) & \text{if } S_t \geq L_T 
\end{cases}$$

where $\lambda_t = S_t/L_T$, $\delta = \delta + r + \frac{1}{2} \sigma^2$, and $\tilde{d}_2^\pm = [\pm \log(\lambda_t) - \tilde{b}(T-t)]/(\sigma \sqrt{T-t})$.

Lemma 3: The density of the first passage time $\tau_L$ is

$$\gamma(y) = \begin{cases} 
-n(\tilde{d}_2^+) \frac{\log(\lambda_t)}{\sigma y^{3/2}} & \text{if } S_t \leq L_T \\
n(\tilde{d}_2^-) \frac{\log(\lambda_t)}{\sigma y^{3/2}} & \text{if } S_t \geq L_T 
\end{cases}$$

The next lemma summarizes a useful integral of the first passage time density. The integral is parameterized by a constant $a$, which appears in expressions for $f(a)$, $\phi(a)$, and $\alpha(a)$ defined in Lemma 4. Elsewhere in the paper, when $f$, $\phi$, and $\alpha$ appear without an argument, they refer to $f(0)$, $\phi(0)$, and $\alpha(0)$, respectively.

Lemma 4:

$$\int_{0}^{t} e^{(a-r)\gamma} \gamma(y) dy = \begin{cases} 
\lambda_0^{2\phi(a)/\sigma^2} N(d_0(a)) + \lambda_0^{2\alpha(a)/\sigma^2} N(d_0(a) + 2 f(a) \sqrt{t}/\sigma) & \text{if } \lambda_0 \leq 1 \\
\lambda_0^{2\phi(a)/\sigma^2} N(-d_0(a)) + \lambda_0^{2\alpha(a)/\sigma^2} N(-d_0(a) - 2 f(a) \sqrt{t}/\sigma) & \text{if } \lambda_0 \geq 1 
\end{cases}$$

where $d_0(a) = [\log(\lambda_0) - f(a) t]/(\sigma \sqrt{t})$, $\lambda_0 = S_0/L_0$, $\tilde{b} = \delta - r + \frac{1}{2} \sigma^2$, $f(a) = (\tilde{b}^2 + 2(a - \sigma^2)^{1/2}$, $\phi(a) = \frac{1}{2} (\tilde{b} - f(a))$, and $\alpha(a) = \frac{1}{2} (\tilde{b} + f(a))$. 
Proof of Corollary 1: The optimal exercise boundary $L \cap B_{\infty}$ is immediate from Theorem 1. For $S_t \geq L \cap B_{\infty}$ immediate exercise is optimal and the option value is $(S_t \wedge L) - K$. For $S_t < L \cap B_{\infty}$ the value of the option can be written as

$$C_t^*(S_t, K, \infty) = (L \cap B_{\infty} - K) E_t^*[e^{-r(\tau - t)}],$$

(25)

where $\tau$ is the hitting time of $L \cap B_{\infty}$. The risk neutral valuation equation (25) follows from the optimal exercise boundary and standard pricing results [see Harrison and Kreps (1979)]. The expectation can be written as

$$E_t^*[e^{-r(\tau - t)}] = \int_{y=0}^{\infty} e^{-r\gamma} \gamma(y) dy = \lim_{T \to \infty} [\lambda_t^{2\phi/\sigma^2} N(d_0) + \lambda_t^{2\alpha/\sigma^2} N(d_0 + 2f\sqrt{T - t}/\sigma)] = \left(\frac{S_t}{L \cap B_{\infty}}\right)^{2\alpha/\sigma^2}.$$

The second equality follows from Lemma 4 with $a = g = 0$ and $\lambda_t = S_t/(L \cap B_{\infty})$. This proves equation (2).

If there are no dividends, $B_{\infty} = \infty$, $\alpha = \sigma^2/2$, and equation (3) follows directly from equation (2). Alternatively, for $\delta = 0$, the discounted stock price is a martingale and by the optional sampling theorem, $S_t = E_t^*[e^{-r(\tau - t)} S_\tau]$ for any stopping time $\tau$. Taking $\tau$ to be the hitting time of the cap $L$ gives $S_t = L E_t^*[e^{-r(\tau - t)}]$. Substituting this formula into equation (25) gives equation (3). ♦

Proof of Theorem 2: By Theorem 1, for $S_t \geq L \cap B_t$ immediate exercise is optimal and the option value is $(S_t \wedge L) - K$. For $S_t < L \cap B_t$ and $t \geq t^*$ optimal exercise occurs at the first time the boundary $B$ is reached or at maturity, so the capped option value is the standard uncapped option value $C_t(S_t)$. For $S_t < L \cap B_t$ and $t < t^*$ the valuation formula (4) is immediate from Theorem 1.

To obtain (5), first define $S^n_t$ to be the process which is followed by $S$ in the absence of dividends. That is, the processes $S$ and $S^n$ are related by $S_t^n = S_t e^{\delta t}$. This can be used to compute the first expectation in equation (4). When $t^* > t$ we have

$$E_t^*[e^{-r(\tau_{L \cap B_t} - t)} (S_{\tau_{L \cap B_t}} - K) 1_{[\tau_{L \cap B_t} < t^*]}] = \int_{y=0}^{t^* - t} e^{-r\gamma} (L - K) \gamma(y) dy = (L - K) \left[\lambda_t^{2\phi/\sigma^2} N(d_0) + \lambda_t^{2\alpha/\sigma^2} N(d_0 + 2f\sqrt{t^* - t}/\sigma)\right].$$

(26)

In (26), $\gamma(y)$ represents the density of the first passage time of $S_t$ to the level $L$. The formula for $\gamma(y)$ is given in Lemma 3 for the case $S_t \leq L$ and $g = 0$. Equation (27) follows from (26) using Lemma 4 with $a = g = 0$. 
The second expectation can be written as
\[
E_t^*[e^{-r(t^*-t)}C_t^*(S_t^*)1_{[t\leq t^*]}) = e^{-r(t^*-t)} \int_{x=0}^{L} C_t^*(x) \, dP[S_t^* \leq x, S_\nu < L \text{ for } \nu \in [t, t^*]] \, dx
\]
\[
= e^{-r(t^*-t)} \int_{x=0}^{L} C_t^*(x) \, u(x, t, t^*) \, dx
\]

The formula for \(u(x, t, t^*)\) in equation (6) in the text follows by differentiating \(U(S_t, x, L, t, t^*)\) with respect to \(x\) (see equation (24) in Lemma 1). ♦

**Proof of Corollary 2:** The first term in equation (10) is the same as the term in (5) in Theorem 2 with \(t^*\) replaced by \(T\).

The remaining terms in equation (10) follow from
\[
E[e^{-r(T-t)}(S_T - K)^+1_{\{\tau_t \geq T\}}]
\]
\[
= \int_{x=0}^{L} e^{-r(T-t)}(x-K)^+ \, dP[S_T \leq x \text{ and } S_\nu < L \text{ for } \nu \in [t, T)]
\]
\[
= \int_{x=K}^{L} e^{-r(T-t)}(x-K)\left[n(d_1^-(x)) - \lambda_t^{1-2(r-\delta)/\sigma^2}n(d_1^-(x))\right] \frac{1}{x \sigma \sqrt{T-t}} \, dx
\]
\[
= \int_{x=K}^{L} e^{-r(T-t)} \frac{1}{\sigma \sqrt{T-t}} \left[n(d_1^-(x)) - \lambda_t^{1-2(r-\delta)/\sigma^2}n(d_1^-(x))\right] \, dx
\]
\[
- Ke^{-r(T-t)}[N(d_1^-(L)) - N(d_1^-(K)) - \lambda_t^{1-2(r-\delta)/\sigma^2}\{N(d_1^-(L)) - N(d_1^+(K))\}].
\]

A simplification of the integral in the previous line gives equation (10) and proves Corollary 2. ♦

**Proof of Theorem 3:** The event \(\{S_t \geq L\}\) is equivalent to the event
\[
\{z \geq \left[\log(L/S_t) - (r-\delta - \frac{1}{2} \sigma^2)(t_e - t) \right] \frac{1}{\sigma \sqrt{t_e - t}}\}.
\]

**Proof of Theorem 4:** We start by considering whether it is optimal to exercise above the cap. At time 0, the perfect foresight value of exercising the option at time \(s\) (when \(S_s > L_s\)) is
\[
f(s) = e^{-rS[t_0 e^{\theta s} - K]}.
\]

For a trajectory such that \(S_t \geq L_t\) for all \(0 \leq t \leq T\), the optimal exercise time is given by \(\hat{t} \equiv \arg\max_{0 \leq s \leq T} f(s)\). In fact, this \(\hat{t}\) is \(t_f^*\) as shown next.

Suppose that \(s < T\) and \(S_s > L_s\). There exists a random variable \(\epsilon(\omega)\) such that \(S_{s+\epsilon(\omega)} > L_{s+\epsilon(\omega)}\) (probability almost surely). Hence, it pays to delay exercise if \(f'(s) > 0\). Defining \(t_f^* = \arg\max_{0 \leq s \leq T} f(s)\), it easy to show that \(f'(s) > 0\) for \(s < t_f^*\) and \(f'(s) < 0\) for \(s > t_f^*\). It follows that
it does not pay to exercise if $S_t > L_t$ and $t < t_f^*$. On the other hand, immediate exercise is optimal if $S_t \geq L_t$ and $t \geq t_f^*$.

The same argument as in the proof of Theorem 1 shows that it is not optimal to exercise at any time $t < T$ when $S_t < L_t \land B_t$. It also shows that exercise is optimal whenever $t \geq t^*$ and $B_t \leq S_t \leq L_t$.

Hence, exercise is only optimal at time $t < t^* \land t_f^*$ if $S_t = L_t$. To show that a $(t_e, t^*, t_f)$ exercise policy is optimal, it remains to be shown that the optimal exercise set at the cap is connected and extends from some $t_e$ to $t^* \land t_f^*$. Lemma 5 which follows asserts exactly this result and hence proves Theorem 4.

**Lemma 5** (Connectedness of the exercise set): Suppose that it is optimal to exercise at time $t_1$ when $S_{t_1} = L_{t_1}$. Then for all times $t_2$ satisfying $t_1 \leq t_2 \leq t^* \land t_f^*$, it is optimal to exercise when $S_{t_2} = L_{t_2}$.

**Proof of Lemma 5**: Without loss of generality, we assume that $t_f^* = T$. Let $\tau(L, t, T)$ denote the optimal time to exercise an option with a cap of $L$ starting at time $t$ which matures at time $T$. Let $C_t^{\tau(L, t, T)}(S, L, T)$ denote the option price under the policy $\tau(L, t, T)$ when the stock price at time $t$ is $S$, the cap function is $L$, and the option matures at time $T$. Define the cap $\bar{L}$ by $\bar{L}_t = L_{t+t_1-t_2}$ for $t \geq t_2$. Finally, let $S^1 = L_{t_1}$ and $S^2 = L_{t_2}$. By the definition of $\bar{L}$, $\bar{L}_{t_2} = S^1$. Figure 7 illustrates these definitions.

Figure 7 ABOUT HERE

**Claim 1**: $L_{t_1} - K \geq C_{t_2}^{\tau(L, t_2, T)}(S^1, \bar{L}, T)$.

**Proof of Claim 1**:

$$L_{t_1} - K = C_{t_1}^{\tau(L, t_1, T)}(S^1, L, T) \quad \text{(since it is optimal to exercise at } t_1)$$
$$\geq C_{t_1}^{\tau(L, t_1, T-(t_2-t_1))}(S^1, L, T-(t_2-t_1)) \quad \text{(American option with a shorter maturity)}$$
$$= C_{t_2}^{\tau(L, t_2, T)}(S^1, \bar{L}, T) \quad \text{(S is a Markovian process)}$$

In the second line, $\tau(L, t_1, T-(t_2-t_1))$ is the optimal exercise policy at time $t_1$ for an option with maturity $T-(t_2-t_1)$ and cap $L$. Since the cap $\bar{L}$ between $t_1$ and $T-(t_2-t_1)$ is the same as the cap $\bar{L}$ between $t_2$ and $T$, the equality in the third line holds.
Claim 2: \( C_{t_2}^{(L,t_2,T)}(S^2, L, T) - C_{t_2}^{(L,t_2,T)}(S^1, \tilde{L}, T) \leq L_{t_2} - L_{t_1} \).

Proof of Claim 2:

\[
C_{t_2}^{(L,t_2,T)}(S^2, L, T) - C_{t_2}^{(L,t_2,T)}(S^1, \tilde{L}, T) \\
\leq C_{t_2}^{(L,t_2,T)}(S^2, L, T) - C_{t_2}^{(L,t_2,T)}(S^1, \tilde{L}, T) \\
\quad \text{(suboptimality of } \tau \equiv \tau(L, t_2, T) \text{ for } C_{t_2}^{(L,t_2,T)}(S^1, \tilde{L}, T))} \\
= E_{t_2}^*[e^{-r(\tau(L,t_2,T)-t_2)}(L_{\tau(L,t_2,T)} - \tilde{L}_{\tau(L,t_2,T)}) 1_{\{\tau(L,t_2,T)<T\} \cap \{\tilde{L}^2 = L_{t_2}\}}] \\
\quad + E_{t_2}^*[e^{-r(\tau(L,t_2,T)-t_2)}((S^2_{\tau(L,t_2,T)} - K)^+ - (S^1_{\tau(L,t_2,T)} - K)^+) 1_{\{\tau(L,t_2,T)<T\} \cap \{\tilde{S}^2 = \tilde{L}_{t_1}\}}] \\
\quad + E_{t_2}^*[e^{-r(T-t_2)}(L_T - \tilde{L}_T) 1_{\{\tau(L,t_2,T) \geq T\} \cap \{\tilde{S}^2 \geq L_{t_2}\}}] \\
\quad + E_{t_2}^*[e^{-r(T-t_2)}((S^2_T - K)^+ - (S^1_T - K)^+) 1_{\{\tau(L,t_2,T) \geq T\} \cap \{\tilde{S}^2 \leq L_{t_2}\}}] \\
\quad \text{(where } \tilde{S}^i_T = S^i e^{(r-\delta - \frac{1}{2}\sigma^2)(\tau - t_2)+\sigma(\tau - z_{t_2})} \text{ for } i = 1, 2 \text{)} \\
\quad \text{and } \tilde{S}^i_T = S^i e^{(r-\delta - \frac{1}{2}\sigma^2)(T-t_2)+\sigma(\tau - z_{t_2})} \text{ for } i = 1, 2) \\
\leq E_{t_2}^*[e^{-r(\tau(L,t_2,T)-t_2)}(S^2_{\tau(L,t_2,T)} - S^1_{\tau(L,t_2,T)}) 1_{\{\tau(L,t_2,T)<T\}}] \\
\quad + E_{t_2}^*[e^{-r(T-t_2)}(S^2_T - S^1_T) 1_{\{\tau(L,t_2,T) \geq T\} \cap \{\tilde{S}^2 \geq L_{t_2}\}}] \\
\quad + E_{t_2}^*[e^{-r(T-t_2)}(S^2_T - S^1_T) 1_{\{\tau(L,t_2,T) \geq T\} \cap \{\tilde{S}^2 \leq L_{t_2}\}}] \\
\quad \text{(since on the event } \tilde{S}^2_T \geq L_{t_2}, \tilde{S}^2_T - \tilde{S}^1_T \geq L_{t_2} - \tilde{L}_T) \\
\leq S^2 - S^1 \\
= L_{t_2} - \tilde{L}_{t_2} = L_{t_2} - L_{t_1}. 
\]

For \( \tau \geq t_2 \) the quantity \( S^2_T - S^1_T \) can be written as \( (S^2 - S^1)e^{(r-\delta - \frac{1}{2}\sigma^2)(\tau - t_2)+\sigma(\tau - z_{t_2})} \) where \( S^2 > S^1 \). Since \( \delta \geq 0 \), the process \( e^{-r(\tau-t_2)}(S^2_T - S^1_T) \) is a supermartingale. Hence for any stopping time \( \tau \geq t_2 \) the last inequality follows. \( \bull \)

Combining Claims 1 and 2 gives

\[
C_{t_2}^{(L,t_2,T)}(S^2, L, T) \leq L_{t_2} - K 
\]

which implies that exercise is optimal at time \( t_2 \) if \( S^2 = L_{t_2} \). This shows that the optimal exercise set is connected and proves Lemma 5. \( \bull \)

Proof of Theorem 5: The option value under the \((t_e, t^*, t_f)\) policy can be written as

\[
C^L(t_e, t^*, t_f) = E_t^*[e^{-r(t_e-t)}C_{t_e,t_f}^u 1_{\{S_{t_e} > L_{t_e}\}} + C_{t_e,t_f}^d 1_{\{S_{t_e} \leq L_{t_e}\}}]. 
\]
Writing $S_{t_e} = S_t \exp\left( (r - \delta - \frac{1}{2} \sigma^2) (t_e - t) + \sigma z \sqrt{t_e - t} \right)$ and $L_{t_e} = L_t \exp[g(t_e - t)]$ implies $S_{t_e} \geq L_{t_e}$ if and only if $z \geq -\tilde{d}^+_2 (\lambda_t, t_e - t)$. Also note that $\lambda_{t_e} = \lambda_t \exp[-\tilde{b}(t_e - t) + \sigma z \sqrt{t_e - t}]$. Using these expressions in the expectation above gives equation (15). Expressions for $C^u_{t_e,t_f}$ and $C^d_{t_e,t_*}$ are proved in Lemmas 6 and 7 which follow.

**Lemma 6:** At time $t_e$ with $S_{t_e} > L_{t_e}$, the value of the option corresponding to the $(t_e, t^*, t_f)$ policy is independent of $t^*$. The value, denoted $C^u_{t_e,t_f}$, is given by equation (16) in the statement of Theorem 5.

**Proof of Lemma 6:**

$$C^u_{t_e,t_f} = E^*_{t_e} \left[ e^{-r(\tau_L - t_e)} (L_{t_L} - K) 1_{\{\tau_L < t_f\}} + e^{-r(t_f - t_e)} (L_{t_f} - K) 1_{\{\tau_L \geq t_f\}} \right]$$

$$= L_{t_e} \int_{y=0}^{t_f} e^{y} y(\gamma) dy - K \int_{y=0}^{t_f} e^{-r} y(\gamma) dy + [L_{t_e} e^{g(t_f - t_e)} - K] e^{-r(t_f - t_e)} E^*_{t_e} [1_{\{\tau_L \geq t_f\}}]$$

Applying Lemma 4 with $a = g$ to the first integral, with $a = 0$ to the second integral, and then applying Lemma 2 to the last expectation proves Lemma 6.

**Lemma 7:** At time $t_e$ with $S_{t_e} \leq L_{t_e}$, the value of the option under the $(t_e, t^*, t_f)$ policy, denoted $C^d_{t_e,t_*}$ is given by equation (17) in the statement of Theorem 5.

**Proof of Lemma 7:**

$$C^d_{t_e,t_*} = E^*_{t_e} \left[ e^{-r(\tau_L - t_e)} (L_{t_L} - K) 1_{\{\tau_L < t_*\}} + e^{-r(t_* - t_e)} C^*(S_{t_*}) 1_{\{\tau_L \geq t_*\}} \right]$$

$$= L_{t_e} \int_{y=0}^{t_*} e^{y} y(\gamma) dy - K \int_{y=0}^{t_*} e^{-r} y(\gamma) dy + \int_{x=0}^{t_*} e^{-r(t_* - t_e)} C^*(x) \mu(x, t_e, t_*) dx$$

The first two integrals can be evaluated using Lemma 4. The term $\mu(x, t_e, t_*)$ represents the density of $S_{t_*}$ given that $\tau_L \geq t_*$. Applying Lemma 1 with a change of variables gives a formula for $P[S_{t_*} \leq x$ and $S_y \leq L_y$ for $y \in [t_e, t_*)]$. Differentiating with respect to $x$ gives the stated formula for $\mu(x, t_e, t_*)$.

**Proof of Theorem 6:** The first part of the proof of Theorem 4 shows that $t_f^*$ is given by

$$t_f^* = \arg \max_{0 \leq s \leq T} f(s), \quad (18)$$

where $f(s) = e^{-r s}[L_0 e^{g s} - K]$. The derivative of $f(s)$ is

$$f''(s) = e^{-r s}[(g - r)L_0 e^{g s} + r K]. \quad (28)$$
Equation (28) implies that $f$ is unimodal. If condition (19) holds, i.e., if $(g - r)L_0e^{\theta T} + rK \geq 0$, then $f'(s) \geq 0$ for all $0 \leq s \leq T$. This means that the marginal value of waiting to exercise is positive, so it is not optimal to exercise above the cap. Hence $t_f^* = T$.

If condition (20) holds, i.e., if $(g - r)L_0 + rK \leq 0$, then $f'(s) \leq 0$ for all $0 \leq s \leq T$. This means that the marginal value of waiting to exercise is negative, so immediate exercise is always optimal at or above the cap. Hence $t_f^* = 0$. Finally, if $0 < t_f^* < T$, $f'(t_f^*) = 0$ which implies equation (21).

The optimal value of $t_e$, denoted $t_e^*$, is given by the solution of the univariate nonlinear program (P):

$$(P) \quad \text{max}_{t_e} \quad C_0^L(t_e, t^*, t_f^*)$$

subject to:

$$0 \leq t_e \leq t^* \land t_f^*$$

The Karush-Kuhn-Tucker Theorem gives necessary conditions for $t_e^*$ to solve (P). If the optimal solution to (P) is an interior solution, i.e., if $0 < t_e^* < t^* \land t_f^*$, then

$$\frac{\partial C_0^L(t_e, t^*, t_f^*)}{\partial t_e} \bigg|_{t_e = t_e^*} = 0. \quad (29)$$

By the Markovian property of the underlying asset process, the optimal solution to (P) is independent of $S_0$. For convenience, we take $S_0 = L_0$, i.e., $\lambda_0 = 1$, in equation (29). Taking the partial derivative of the expression for $C_0^L(t_e, t^*, t_f^*)$ in equation (15) and setting the result to zero at $t_e = t_e^*$ gives the integral equation (22). If $t_e^* = t^* \land t_f^*$, then $\partial C_0^L(t_e, t^*, t_f^*)/\partial t_e \geq 0$ when evaluated at $t_e = t^* \land t_f^*$. If $t_e^* = 0$ is the optimal solution to (P), then $\lim_{t_e \to 0} \partial C_0^L(t_e, t^*, t_f^*)/\partial t_e \leq 0$. ✷
Footnotes

1. The payoff is assumed to be \((S_t \wedge L) - K)^+\) even when the option is exercised out-of-the-money, i.e., when \(S_t \leq K\). This assumption is for expositional convenience only. It eliminates the need to describe exercise policies using separate cases for \(S_t \leq K\) and \(S_t > K\). In reality, the option would never be exercised when \(S_t \leq K\).

2. Suppose an investor purchases one call, shorts one unit of the underlying asset, and invests the strike price in the riskless bond. If the value of the call were equal to the immediate exercise value, these transactions would have zero cost. Now if the investor closes the position at the first hitting time of the time-dependent boundary or at maturity, the net cash flow is strictly positive, which implies an arbitrage opportunity. Hence, no-arbitrage means that immediate exercise is not optimal for \(S_t < L_t\).

3. An explicit expression for \(B_\infty\) is \(K(b + f) / (b + f - \sigma^2)\), where \(b\) and \(f\) are defined in (9) below.

4. For \(S_t < L\), equation (3) in the absence of dividends is valid for more general price processes. In fact, the last part of the proof of Corollary 1 in the Appendix shows that the equation holds for Itô price processes \(dS_t = S_t[r dt + \sigma_t dW_t]\), where \(r\) is constant and \(\sigma_t\) is progressively measurable with respect to \(W\). We thank Bjorn Flesaker for pointing out the generality of equation (3).

5. Since \(L\) is constant and \(B_t\) is continuous and strictly decreasing in \(t\), there cannot be more than one solution \(t^*\).

6. More general results for time varying and random caps in the absence of dividends are given in Broadie and Detemple (1993a).

7. Note that \(\hat{b}\) differs from \(b\) because of \(g\). Also \(f\), \(\phi\), and \(\alpha\) have slightly different meanings than before because of \(\hat{b}\) in their definitions.

8. Explicit expressions for all of the partial derivatives in equation (22) can be obtained from the authors.

9. For \(t < t^*\) the cap \(L_t\) is never used.

*The hedge ratio for $S_0 = 59.99$ is 0.79. The derivative is discontinuous at $S_0 = L$.
